Build the Stan model

There are multiple ways to estimate a Stan model in R, but I choose to build the Stan code directly rather than using the brms or rstanarm packages. In the Stan code, we need to define the data structure, specify the parameters, specify any transformed parameters (which are just a function of the parameters), and then build the model – which includes laying out the prior distributions as well as the likelihood.

In this case, the model is slightly different from what was presented in the context of a mixed effects model. This is the mixed effects model:

```
\label{eq:lik} $$ \left\{ y_{ik} = \alpha_k + \beta_k x_{ik} + e_{ik} \right\} $$ \left\{ y_{ik} = \beta_k + \beta_k \right\} $$ \left\{ y_{ik} \cdot N(0, \beta_k^2), v_k \cdot N(0,\beta_k^2) \right\} $$ In this Bayesian model, things are pretty much the same: $$ \left\{ y_{ik} \cdot N(\alpha_k + \beta_k x_{ik}, \beta_k^2) \right\} $$ \left\{ y_{ik} \cdot N(\beta_k + \beta_k x_{ik}, \beta_k^2) \right\} $$ \left\{ y_{ik} \cdot N(\beta_k x_{ik}, \beta_k^2) \right\} $$ \left
```

The key difference is that there are prior distributions on \(\Delta\) and \(\tau\), introducing an additional level of uncertainty into the estimate. I would expect that the estimate of the overall treatment effect \(\Delta\) will have a wider 95% CI (credible interval in this context) than the 95% CI (confidence interval) for \(\tau\) in the mixed effects model. This added measure of uncertainty is a strength of the Bayesian approach.

```
data {
 int N;
                   // number of observations
                    // number of studies
 int K;
 real y[N];
                            // vector of continuous outcomes
 int kk[N]; // study for individual
 int x[N]; // treatment arm for individual
parameters {
 vector[K] beta;
                            // study-specific intercept
 real tau; // variation of treatment effects
}
transformed parameters{
 vector[N] yhat;
 for (i in 1:N)
    yhat[i] = beta[kk[i]] + x[i] * delta[kk[i]];
}
model {
 // priors
 sigma \sim normal(0, 2.5);
 beta \sim normal(0, 10);
 tau ~ normal(0, 2.5);
 Delta \sim normal(0, 10);
 delta ~ normal(Delta, tau);
 // outcome model
 for (i in 1:N)
   y[i] ~ normal(yhat[i], sigma[kk[i]]);
}
```

Generate the posterior distributions

rt <- stanc("model.stan")</pre>

sm <- stan model(stanc ret = rt, verbose=FALSE)</pre>

With the model in place, we transform the data into a list so that Stan can make sense of it:

Finally, we can sample data from the posterior distribution:

Check the diagonstic plots

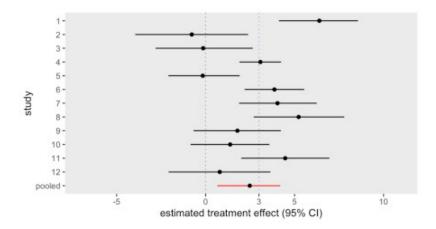

Before looking at any of the output, it is imperative to convince ourselves that the MCMC process was a stable one. The *trace* plot is the most basic way to assess this. Here, I am only showing these plots for \(\Delta\) and \(\tau\), but the plots for the other parameters looked similar, which is to say everything looks good:

Look at the results

It is possible to look inspect the distribution of any or all parameters. In this case, I am particularly interested in the treatment effects at the study level, and overall. That is, the focus here is on \(\Delta\), \(\delta_k\), and \(\tau\).

```
pname <- c("delta", "Delta", "tau")</pre>
print(fit, pars=pname, probs = c(0.05, 0.5, 0.95))
## Inference for Stan model: model.

## convergence, Rhat=1).
```

The forest plot is quite similar to the one based on the mixed effects model, though as predicted, the 95% CI is considerably wider:

As a comparison, here is the plot from the mixed effects model estimated using the nlme package in the previous post. The bootstrapped estimates of uncertainty at the study level are quite close to the Bayesian measure of uncertainty; the difference really lies in the uncertainty around the global estimate.
